Abstract. Combination of multiple evidences (multiple query formulations, multiple retrieval schemes or systems) has been shown (mostly experimentally) to be effective in data fusion in information retrieval. However, the question of why and how combination should be done still remains largely unanswered. In this paper, we provide a model for simulation and a framework for analysis in the study of data fusion in the information retrieval domain. A rank/score function is defined and the concept of a Cayley graph is used in the design and analysis of our framework. The model and framework have led us to better understanding of the data fusion phenomena in information retrieval. In particular, by exploiting the graphical properties of the rank/score function, we have shown analytically and by simulation that combination using rank performs better than combination using score under certain conditions. Moreover, we demonstrated that the rank/score function might be used as a predictive variable for the effectiveness of combination of multiple evidences.

Keywords: information retrieval (IR), data fusion (DF), rank combination, score combination, multiple evidences, evidence combinations, permutation, symmetric group, Cayley graphs and digraphs, rank/score function

# 1. Introduction

Information retrieval can be considered as a problem of inference (van Rijsbergen 1986). It is a process concerned with estimating, given available evidence about things, such as information need and documents, the likelihood (or probability) of relevance of a document to the information need. As such, different query formulations constitute different sources of evidence that could be used to infer the probable relevance of a document to an information need. This can be generalized to include any source of evidence that might be used for IR such as the evidence of different retrieval techniques, different document representation techniques, or different IR systems.

\*Authors wish to dedicate this paper to the memory of our friend and colleague Professor Jacob Shapiro, who passed away September 2003.

Figure 1. Information retrieval (IR) process.

Figure 2. Multiple formulations and multiple schemes.

Information retrieval can be viewed as a process which takes a query (Q) as an input and produces the output which is a list of documents or results (R) (see figure 1(a)). The IR process entails a query formulation (F) or representation and a scheme or system (S) which processes the query formulation in order to obtain results (R) (see figure 1(b)).

With the advent of computer science and information technology (in particular, database technology and information retrieval technology), it has become feasible and possible to improve information retrieval system performance by considering multiple formulations and multiple schemes. Figure 2 depicts three such possibilities.

MFSS—multiple formulations single scheme (figure 2(a)), SFMS—single formulation multiple schemes (figure 2(b)), and MFMS—multiple formulations multiple schemes (figure 2(c)). However, very few of the developments have actually investigated the effect of multiple formulations and/or multiple retrieval schemes on performance.

Saracevic and Kantor (1988) stated explicitly that taking into account the different results of the different formulations could lead to retrieval performance better than that of any of the individual query formulations. The project reported in Belkin et al. (1993) studied the effect of combining multiple representations of information problems on the performance of the INQUERY probabilistic inference network retrieval engine. Although their results showed that, in general, progressive combinations of query formulations lead to progressive improvement in retrieval performance, the INQUERY results (INQC) were substantially better than those of the combined Boolean queries. The authors then considered the issue of combining INQC and the combined Boolean queries as two different sources of evidence. The overall retrieval performance became worse when more weight was given to the Boolean query evidence. However, the performance was improved when fractional weights were given to the combined Boolean queries.

Belkin et al. (1994) and Fox and Shaw (1994) investigated the effect of combination of multiple representations of TREC topics on retrieval performance. Both projects found that the best method of combination often led to results that were better than the best performing single query. However, they indicated that choosing the best query often results in significant performance differences from combined queries. They also pointed out that in any single run there are always instances of combined queries performing better than the best, and on average combination does better. Belkin et al. (1995) reported on two studies conducted at Rutgers University (Belkin et al. 1994) and at Virginia Tech (Fox and Shaw 1994) that investigated the effect on retrieval performance of combination of multiple representations of TREC-2 topics. When dealing with query combination, the rules used (CombSUM, CombANZ, and CombMNZ) were based on similarity scores between a topic and a document. On the other hand, when dealing with multiple evidences from different schemes (or systems), combinations (MAX, MIN and MED) were based on rank information. Encouraged by the interesting and generally positive results of the two separate studies involving combination of evidences (using similarity scores) or data fusion (using rank information), Belkin et al. (1995) performed two other experiments and had the following observations:

*Remark 1.1.* (a) When different systems are commensurable, combination using similarity scores is better than combination using only ranks; (b) when multiple systems have incompatible scores, a combination method based on ranked outputs rather than the scores directly is the proper method for combination; and (c) although results from the experiments for combination of results from different databases are encouraging, it is not clear that such combination is possible among systems that have different methods for computing similarity scores.

The paper by Pfeifer et al. (1996) gave a review of known similarity measures in a search for proper names. Their experiments (on measures dealing with phonetic similarity, typing errors, and plain string similarity) showed that all three approaches perform significantly better than a system based on exact-match searches only. They suggested that further improvements are possible by combining different methods. Although they realized that combining two or three different similarity measures seems to be very promising, they indicated that further work for maintaining and searching one or two more methods has to be considered.

Lee (1997) presented the rationale for evidence combination that different runs return similar sets of relevant documents but retrieve different sets of non-relevant documents. He also investigated the effect of using ranks instead of using similarity on retrieval effectiveness. In particular, he showed experimentally that in some circumstances, using ranks works better than using similarity. He also investigated the effect of using rank instead of similarity on retrieval effectiveness and found that:

*Remark 1.2.* Data fusion using rank works better than using similarity scores if the runs in the combination have 'different' rank-similarity curves.

In their study of the problem of predicting, in advance, whether combination (or fusion) of two or more retrieval schemes will be worth doing, Ng and Kantor (1998) identified:

*Remark 1.3.* Two predictive variables for the effectiveness of the combination: (a) a listbased measure of output dissimilarity, and (b) a pair-wise measure of the similarity of the performance of the two schemes. In a subsequent study, Ng and Kantor (2000) investigated the prediction power of these two variables using symmetrical data fusion and receiver operating characteristic (ROC) curve. Using precision at the 100th document,  $P_{@100}$ , to represent efficacy similarity, they use ratio  $P_1/P_h$  ( $P_1$  and  $P_h$  are  $P_{@100}$  for the lower and higher performance schemes respectively) as a variable to measure the similarity of performance of the two IR schemes. Although they found that most of the positive cases have ratio of precision  $P_1/P_h$  close to 1, they also stated that the two predictive variables do not completely determine whether simple (linear) and symmetric data fusion will be effective.

The LC (linear combination) model for fusion of IR systems combines the results lists of multiple IR systems by scoring each document with a weighted sum of the scores from each of the component systems. Vogt and Cottrell (1999) studied the problem of predicting the performance of a combined system. Their analysis supports the following:

*Remark 1.4.* An LC model should only be used when the systems involved have high performance, a large overlap of relevant documents, and a small overlap of non-relevant documents.

Previous empirical and experimental results (including those reviewed in this section) have achieved certain statistical success in understanding the effectiveness of data fusion (with multiple formulations of queries, or multiple schemes, or in different runs) in information retrieval. However, the general questions of "why" and "how" DF in IR can be effective still remain unanswered. All these indicate that the problem involves tremendously high complexity and dimensionality. They have become both quantitatively and qualitatively difficult to trace. In an IR system (see figure 1), different schemes (systems or engines) can use different techniques (or algorithms) to measure the likelihood or probability of relevance of a document to a given query. Moreover, the choices of techniques (or algorithms) rely heavily on the application domain they are applied to or used in. This situation is complicated by having a variety of multiple formulations of the information need and a large and multi-faceted collection of documents (see figure 2(a)-(c)). Multiple representations (or query formulations) can occur either as a result of the interpretation of the original need by multiple experts or as disjoint or non-disjoint subsets from the partition of the original query (such as a long query). In both cases, they also involve semantic consideration. On the other hand, the document space consists of not only large and different structured database systems but also a variety of sites (such as the World Wide Web) located in different networks and different countries.

In this paper, we continue the study of the problem of data fusion (DF) in information retrieval domain (see figure 2). On one hand, we restrict ourselves to information retrieval using similarity measures to search for proper (relevant) documents in the databases or on the World Wide Web when presented with an information need (a query). On the other hand, even though we include the general MFMS setting (see figure 2(c)), we only consider the case of combining results of search in the same database or search space. In general, we have found:

*Remark 1.5.* (a) Different formulations (or representations) can be derived from the same query by different experts. But they can also be obtained from different (disjoint or

non-disjoint) subsets of the same query; and (b) the search can be based on different formulations (see figure 2(a)) or/and using different schemes (or systems) (see figure 2(b) and (c)) on the same database (or on the World Wide Web).

Data fusion is a process (acquisition, design, and interpretation) of combining information gathered by multiple agents (sources, schemes, sensors or systems) into a single representation (or result). Data fusion has been used in pattern recognition where results from multiple recognizers (or classifiers) with different feature extracts are combined so as to achieve better results (Xu et al. 1992). Multiple sensor DF has been studied in various application domains such as signal detection, target tracking, image processing, surveillance and defense applications (Hsu et al. 2003, Lyons et al. 2003, Varshney 1997).

The concept of data fusion has been used, as mentioned above, in information retrieval to study the combination of multiple evidences resulting from different query formulations or from different schemes (Belkin et al. 1993, 1994, 1995, Fox and Shaw 1994, Kantor 1998, Lee 1997, Ng and Kantor 1998, 2000, Pfeifer et al. 1996). Many empirical studies have been performed and various results have been obtained. While some of the major issues related to the questions such as why and how multiple evidences should be combined remain unanswered, researchers have come to realize the advantage and benefit of combining multiple evidences.

Our approach aims to study the problem of when DF in IR is worth doing and how fusion should be done. We take the modeling approach, which will encompass several fundamental issues related to the theoretic treatment of the complex problem. We establish a model based on Cayley graphs and digraphs (called CG model) with the following characteristics:

*Remark 1.6.* (a) Each of the multiple evidences (say evidence A) is represented as a ranked list of two functions  $(x, r_A(x))$  and  $(d, s_A(d))$  indicating ranks with the *rank function* (the document  $r_A(x)$  is ranked x), and documents with the *score function* (the document d has similarity score  $s_A(d)$ ) respectively; and (b) assuming that there are *n* different documents,  $r_A(x)$  is then considered as a permutation of these *n* documents and  $s_A(d)$  is a function from the set of *n* documents to the set of real numbers.

Our model uses a ranked list which consists of a rank function (as a permutation in the set of all permutations of *n* elements  $S_n$ ) and a score function (which is the similarity score of the document). We perform analytical study and simulation of the DF of different kinds of ranked lists and investigate the effectiveness of these DF's. We also study DF techniques using rank vs. score combination and explore further the question of when and why one kind of combination is better than the other. We believe that our model and approach will provide better understanding of the phenomena surrounding the issue of effectiveness of DF in information retrieval.

In Section 2, we describe our data fusion framework which includes a data fusion model and architecture of combining two evidences (i.e. two ranked lists). We also give definition of a Cayley graph and introduce the concept of rank/score function. Section 3 gives an analytical result which strongly supports the advantage of using the framework. Experimental results are included in Section 4. More detailed discussions and remarks are summarized in Section 5 which concludes the paper.

# 2. Data fusion model and architecture

We first review and define some of the notations and terminologies, which will be used in latter sections. For positive integers k and n, let  $[n] = \{1, 2, 3, 4, ..., n\}$  and [k, n] = [n] - [k - 1]. Similarly, we define  $[d_n]$  to be  $\{d_1, d_2, ..., d_n\}$ . A permutation  $\alpha$  on [n] is an one to one mapping from [n] to itself. It can be written as the following different, but equivalent, forms:

$$\frac{x \qquad 1 \qquad 2 \qquad 3 \qquad \dots \qquad n}{\alpha(x) \quad \alpha(1) \quad \alpha(2) \quad \alpha(3) \ \dots \ \alpha(n)}$$

and

$$\begin{pmatrix} 1 & 2 & 3 & 4 & \dots \\ \alpha_1 & \alpha_2 & \alpha_3 & \alpha_4 & \dots \\ \alpha_n \end{pmatrix} = [\alpha_1, \alpha_2, \alpha_3, \alpha_4, \dots, \alpha_n] = [\alpha_1 & \alpha_2 & \alpha_3 & \alpha_4 \dots \\ \alpha_n \end{bmatrix}$$

It can also be written as the product of disjoint cycles each consisting of elements from [n]:

$$\alpha = (\alpha_{11} \alpha_{12} \dots \alpha_1 k_1)(\alpha_{21} \alpha_{22} \dots \alpha_2 k_2)(\alpha h_1 \alpha h_2 \dots \alpha h k_h)$$

where

$$\alpha(\alpha_{ij}) = \alpha_i(j+1), \ \alpha(\alpha_i k_i) = \alpha_{i1} \text{ and } \sum_{i=1}^h k_i = n.$$

For example, when  $\alpha$  is a permutation on the set of numbers  $\{1, 2, 3, 4, 5, 6\}$ , we have

and

$$\alpha = \begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 4 & 6 & 3 & 5 & 1 & 2 \end{pmatrix} = [4, 6, 3, 5, 1, 2] = (1 \ 4 \ 5)(2 \ 6)(3) = (1 \ 4 \ 5)(2 \ 6).$$

Often a cycle of length one is ignored without any ambiguity. We also adopt the convention that each permutation is written interchangeably (without confusion) as an ordered list of elements of [n] and as concatenations of cycles of elements of [n]. Let  $S_n$  be the set of all permutations on [n]. Define binary operation "\*" between two permutations  $\alpha$  and  $\beta$  in  $S_n$  as  $(\alpha * \beta)(x) = \alpha(\beta(x))$ . The set  $S_n$  together with the binary operator "\*" forms a group. It is also called the *symmetric group*  $S_n$  of order n. We now define the concept of a group and a graph.

*Definition 2.1.* Let  $\Gamma$  be a finite set of *n* elements and \* be a binary operation in  $\Gamma$ . $\Gamma$  is said to be a *group* if it satisfies the following properties:

(a) for every *a*, *b* ∈ Γ, *a* \* *b* ∈ Γ,
(b) for every *a*, *b*, *c* ∈ Γ, (*a* \* *b*) \* *c* = *a* \* (*b* \* *c*),

454

- (c) there exists an identity element **e** in  $\Gamma$ , such that  $\mathbf{e} * a = a * \mathbf{e} = a$  for all a in  $\Gamma$ , and
- (d) for every  $a \in \Gamma$ , there exists  $b_l$  and  $b_r$  such that  $b_{l*}a = \mathbf{e}$  and  $a*b_r = \mathbf{e}$ . The two elements  $b_l$  and  $b_r$  are called the *left inverse* and *right inverse* of the element a respectively.

The two properties in (a) and (b) are called *closure property* and *associativity* respectively. If for any two elements a, b in  $\Gamma$ , a \* b = b \* a, then  $\Gamma$  is said to be *commutative*. Often in this case,  $\Gamma$  is said to be an *Abelian group*.

*Definition 2.2.* Let V be a set of n elements, E a set of collection of subsets with 2 distinct elements from V, and A a set of collection of ordered pairs with distinct elements from V. For simplicity, we assume the subsets in E (and the ordered pairs in A) are distinct. G = (V, E) and D = (V, A) are said to be a *graph* and a *directed graph* respectively, with E as the edge set of G and A as the arc set of D.

We note that the symmetric group  $S_n$  of order *n* is a special case of a kind of algebraic entity called *permutation group*. For definition and properties of a permutation group, the readers are referred to the book by Biggs and White (1979).

The symmetric group  $S_n$ , when imposed a metric, would become a metric space. For example, when the metric is Kendall distance  $d_k(\alpha, \beta)$  which counts the number of discordant pairs between  $\alpha$  and  $\beta$ ,  $S_n$  then becomes a metric space denoted as  $(S_n, d_k)$ . However, since the metric space  $(S_n, d_k)$  is discrete and it is a special case of a more general structure, we define the concepts of a Cayley graph and a Cayley digraph as follows:

Definition 2.3. Let  $\Gamma$  (or  $\Gamma'$ ) be a group and *S* (or *S'*) a generating set which does not include identity element of  $\Gamma$  (or  $\Gamma'$ ). *Cayley digraph*  $G(\Gamma, S)$  is the directed graph with node set  $V(G) = \Gamma$  and arc set  $A(G) = \{(a, b) \mid a, b \in \Gamma, ba^{-1} \in S\}$ . The *Cayley graph*  $G'(\Gamma', S')$  is an undirected graph with node set  $V(G') = \Gamma'$  and edge set  $E(G') = \{(c, d) \mid c, d \in \Gamma', cd^{-1}, dc^{-1} \in S\}$ .

The study of Cayley graphs and digraphs, sometimes under the name Cayley color-group or Cayley diagrams, can be dated to the 1940's. Recent survey and treatments can be found in Biggs and White (1979) and Grammatikakis et al. (2001), Chap. 6.4, and Heydemann (1997). In our applications here, we are more concerned with the case of Cayley graph where  $\Gamma = S_n$ , the symmetric group, and S is a generating set with transpositions. Two kinds of S we are most interested in are  $T_1$  and  $T_2$ :

$$T_1 = \{(t, t+1) \mid t \in [1, n-1]\},\$$

and

$$T_2 = \{(i, j) \mid i, j \in [n], i \neq j, i < j\}.$$

We are using the Cayley graph  $G(S_n, T)$ ,  $T = T_1$  or  $T = T_2$ , as the rank space.  $G(S_n, T_1)$ and  $G(S_n, T_2)$  are closely related to the two metric spaces  $(S_n, d_k)$  (defined by Kendall distance  $d_k(\alpha, \beta)$ ) and  $(S_n, d_{cay})$  (using Cayley's distance  $d_{cay}(\alpha, \beta)$ ). Both distances  $d_k$  and  $d_{cay}$  can be found in Marden (1995). While  $d_k(\alpha, \beta)$  counts the number of discordant pairs between  $\alpha$  and  $\beta$ ,  $d_{cay}(\alpha, \beta)$  counts the minimum number of arbitrary pair-wise interchanges needed to bring the  $\alpha$  order  $[\alpha_1, \alpha_2, \ldots, \alpha_n]$  to the  $\beta$  order  $[\beta_1, \beta_2, \ldots, \beta_n]$ .

When  $d_k(\alpha, \beta) = 1$ ,  $\alpha$  and  $\beta$  are related to (or incident with) each other by an adjacent transposition  $\tau$  in  $S_n$ . It follows that  $(S_n, T_1)$  is a graph where  $S_n$  is the set of all permutations of [n],  $[\alpha_1, \alpha_2, \ldots, \alpha_n]$ , and  $T_1 = \{(t, t + 1) \mid t \in [1, n - 1]\}$  defines the adjacency among two nodes  $\alpha$  and  $\beta$  ( $\alpha \sim \beta$  if  $\beta = \alpha \circ \tau$  for some  $\tau$  in  $T_1$ ). In fact, this means that Kendall distance  $d_k(\alpha, \beta)$  is equivalent to the graph distance  $d(\alpha, \beta)$  calculated in the Cayley graph  $G(S_n, T_1)$ . The same kind of equivalence occurs when the distance is the Cayley distance and the adjacency in the graph is defined using the sets of transpositions  $T_2$ . Since the Cayley distance  $d_{cay}(\alpha, \beta)$  counts the minimum number of arbitrary pair-wise interchanges needed to bring the order of  $\alpha$  to the order of  $\beta$ , the pair-wise interchanges are the permutations which are transpositions  $T_2 = \{(i, j) \mid i, j \in [n], i < j, i \neq j\}$ . Hence the Cayley graph  $(S_n, T_2)$  is equivalent to the metric space  $(S_n, d_{cay})$ .

We note that although Cayley distance  $d_{cay}(\alpha, \beta)$  and Cayley graph (and Cayley digraph) share the same name "Cayley", they are different in the sense that the former defines a distance between the rankings (or permutation) and the latter defines a graph on a group of permutations.

In our approach of studying DF in information retrieval, a ranked list consists of a rank function and a score function. A rank function  $r_A(x)$  is a ranking of the documents in  $D = \{d_1, d_2, \ldots, d_n\}$ , where the document  $d = r_A(x)$  is assigned the rank of x. A score function  $s_A(d)$  is the similarity score assigned to the document d. Although often we use the numerical subindices to denote the documents, it is easy to confuse document ordering and ranking. In order to alleviate this problem, we use  $d_1, d_2, \ldots, d_n$  to indicate ordering of the *n* documents and when there is no confusion,  $1, 2, 3, \ldots, n$  are used to mean  $d_1, d_2, \ldots, d_n$ . Hence the two functions, rank function and score function,  $(r_A(x) \text{ and } s_B(d) \text{ in Remark 1.6})$ , are listed as follows (when  $r_A(x)$  is a function from [10] to  $[d_{10}]$  and  $s_A(d)$  is a function from  $[d_{10}]$  to [0, 1] = the set of real numbers between and including 0 and 1.

d	$d_1$	$d_2$	d <sub>3</sub>	$d_4$	$d_5$	$d_6$	$d_7$	$d_8$	$d_9$	$d_{10}$
$s_A(d)$	0.1	1.0	0.9	0.4	0.7	0.6	0.2	0.5	0.1	0.3

We are now ready to define the concept of a rank/score function.

Definition 2.4. The rank/score function  $f_A$  for the system A is a function from [n] to  $[0, s] = \{x \in R^+ \text{ and } 0 \le x \le s\}$ , where s is the highest score the system A can have in the set of non-negative real numbers  $R^+$  such that  $f_A(x) = (s_A \circ r_A)(x) = s_A(r_A(x))$  for x in [n].

456

and

It follows that  $f_A$  has the following values when n = 10 in the example above.

x	1	2	3	4	5	6	7	8	9	10
$f_A(x)$	1.0	0.9	0.7	0.6	0.5	0.4	0.3	0.2	0.1	0.1

For a ranked list A with  $r_A(x)$  and  $s_A(d)$  and  $q \in [n]$ , we define the following two parameters to measure the performance of the system (or scheme) of the ranked list A.

*Definition 2.5* (Precision at q and average precision). Let  $A_{(k)} = \{r_A(i) \mid i \leq k\}$  and  $A^{(k)} =$  smallest set  $A_{(j)}$ ,  $1 \leq j \leq n$ , s.t.  $|A_{(j)} \cap \text{Rel}| = k$ , where Rel = set of all documents that are judged to be relevant. If |Rel| = q for some integer  $q(0 < q \leq n)$ , we define two measures of performance for a system A as follows:

Precision at q of A : 
$$P_{@q}(A) = \frac{|\text{Rel} \cap A_{(q)}|}{q}$$
  
Average precision of A :  $P_{avg}(A) = \frac{\sum_{i=1}^{q} \frac{i}{|A^{(i)}|}}{q}$ 

For two ranked lists A and B, we present two different ways of combining A and B. One uses rank combination and the other uses score combination.

Definition 2.6 (Rank combination). Given two ranked lists A and B with  $r_A(x)$ ,  $s_A(d)$  and  $r_B(x)$ ,  $s_B(d)$  respectively, let  $g_{AB}(d) = (1/2)[r_A^{-1}(d) + r_B^{-1}(d)]$ . Sort the array  $g_{AB}(d)$  in ascending order and let  $s_g(d)$  be the resulting array. Since the two arrays  $s_g(d)$  and  $f_g(x)$  are equivalent to each other with  $r_C(x) = d$ , the ranked list C which is the combination of A and B using ranks has the rank function  $r_C(x) = d$  with  $f_g(x) = s_g(r_C(x))$ .

Definition 2.7 (Score combination). Given two ranked lists A and B with  $r_A(x)$ ,  $s_A(d)$  and  $r_B(x)$ ,  $s_B(d)$  respectively, let  $h_{AB}(d) = (1/2)[s_A(d) + s_B(d)]$ . Sort the array  $h_{AB}(d)$  in descending order and let  $s_h(d)$  be the resulting array. Since the two arrays  $s_h(d)$  and  $f_h(x)$  are equivalent to each other with  $r_D(x) = d$ , the ranked list D which is the combination of A and B using scores has the rank function  $r_D(x) = d$  with  $f_h(x) = s_h(r_D(x))$ .

We illustrate the above two definitions with the example in figure 3 for a special case n = 10. Note that each of the two rank functions  $g_{AB}(x)$  and  $h_{AB}(x)$  may contain duplicate values (such as in  $g_{AB}(x)$  in figure 3(c)). When this happens, we use the convention of choosing the smaller rank in the inverse mapping  $g_{AB}^{-1}$  or  $h_{AB}^{-1}$ . Therefore in figure 3(d), we would pick " $d_1$ " first and then " $d_8$ " because  $g_{AB}^{-1}(f_g(6)) = g_{AB}^{-1}(6.5) = \{d_1, d_8\}$ .

From Definition 2.4, the rank/score function  $f_A$  is a function from [n] to  $[0, s] = \{x \in R^+$ and  $0 \le x \le s\}$  and is independent of the ranked or ordered documents. The function  $s_A(d)$ is then obtained as  $s_A(d) = f_A(r_A^{-1}(d))$ . Figures 3(a) and (b) give two examples for  $s_A(d)$ and  $s_B(d)$ .

Figure 4 gives four rank/score functions grouped in two different settings to show the contrast. The two functions in figure 4(a) are taken from the two score functions in figures 3(a) and (b). The two examples in figure 4(b) have n = 500 and s = 100.

#### *Figure 3.* Combinations using rank vs. score, n = 10.

Our approach to the study of effectiveness of DF in IR consists of a model of simulation and analysis and an architecture summarized in figure 5. We use the symmetric group  $S_n$  as our sample space (or sometimes called rank space) with respect to *n* documents. Since the total number of possible rank data written as permutations is n! which is computationally intractable, we use the diagram in figure 5 to simulate the phenomena. Two basic rankers (or ranked lists) are used (called A and B). Ranker A has a rank function  $r_A(x)$ , a score function  $s_A(d)$ , and the performance P(A),  $P_{@q}(A)$  or  $P_{avg}(A)$ . Ranker B is represented in the same fashion. Ranked lists C and D are rank combinations and score combinations of A and B respectively as defined in Definitions 2.6 and 2.7. By employing different variations of A

(b) Two rank/score functions with n=500 and s=100

Figure 4. Four rank/score functions in two different groups.

and B, we hope to be able to extend and generalize our results. In Section 4, we will have results of our simulation in two cases. The first case deals with the situation where  $r_A(x)$  is fixed as the identity permutation and  $f_A(x)$  is also fixed as a straight line passing through points (1, s) and (n, 0) in the rank/score function graph. In the second case,  $f_A(x)$  is fixed as in the first case, but  $r_A(x)$  is obtained as a random permutation. In the next section (Section 3), we will show that when  $r_B = t \circ e_A$ , the composition of  $t \in T_2$  and the identity function  $e_A, f_B(x)$  has one single turning point (a, b), and q < a with certain conditions, then the performance of the combination by ranks is always better than that of the combination by score, i.e.  $P_{@q}(C) \ge P_{@q}(D)$ .

# 3. Analysis of combination methods

In this section, we take the general view as stated in Remark 1.6. As such, each evidence A is presented as two functions  $r_A(x)$  and  $s_A(d)$  indicating ranks with ranked documents and documents with their similarity scores for n distinct documents. Each rank function

Figure 5. DF architecture.

 $r_A(x) = [A_1, A_2, A_3, \dots, A_n]$  is then considered as a permutation of the *n* documents (or objects in general). Therefore,  $r_A(x)$  is considered an element in the rank space  $S_n$  and a node in the Cayley digraph  $G(S_n, T_1)$  (see Definition 2.3 and definition of  $T_1$ ). Armed with the framework described in Section 2 and previous results discussed in Section 1, we are now able to formulate the central problems in the study of data fusion in information retrieval domain. Let *A* and *B* be two evidences presented as  $[n], r_A(x), s_A(d)$  and  $[n], r_B(x), s_B(d)$  respectively. These are also considered as nodes in the Cayley digraph  $G(S_n, T)$  for some *T*. Let *C* and *D* be the results of fusion from *A* and *B* defined in Definition 2.6 and Definition 2.7 respectively. Let P(C) and P(D) be the performance measurement defined in Definition 2.5 (see also figure 5). We summarize Remarks 1.1–1.6 and ask the following questions:

*Remark 3.1.* For what A and B, P(C) (or P(D))  $\geq \max\{P(A), P(B)\}$  and for what A and B,  $P(C) \geq P(D)$ ?

Since the rank space  $S_n$  has n! elements, the number of possible (A, B) pairs is of order  $(n!)(n! - 1)/2 = O((n!)^2)$  which is computationally unmanageable. In the following section (Section 4), we will study the problem for two different cases. In particular, we will investigate in Section 4 by simulation the performance of C (and of D) for two cases: *Case* 4.1:  $r_A = e_A$  the identity permutation and  $r_B =$  random, and *Case4.2*:  $r_A =$  random and  $r_B =$  random. Actual values we used are n = 500, s = 100 with precision at 50 ( $P_{@50}$ ) and average precision ( $P_{avg}$ ). Among the many results and phenomena observed from these simulations, we see the following pattern:

*Remark 3.2.* Let *A* and *B* be represented as  $r_A$ ,  $s_A$  and  $r_B$ ,  $s_B$  respectively. Let *C* and *D* be obtained and represented as  $r_C$ ,  $s_C$  and  $r_D$ ,  $s_D$  respectively as in figure 5 in Section 2. As long as  $f_A$  and  $f_B$  are "far apart" and  $q \sim n/10$ , then  $\%(P_{@50}(C) > P_{@50}(D)) >> \%(P_{@50}(C) < P_{@50}(D))$  and  $\%(P_{avg}(C) > P_{avg}(D)) >> \%(P_{avg}(C) < P_{avg@50}(D))$  in the case when  $r_A = e_A$  and  $r_B$  = random. In the cases that  $r_A$  = random and  $r_B$  = random,  $\%(P_{avg}(C) > P_{avg}(D)) > \%(P_{avg}(C) > P_{avg}(D))$ .

We now analyze the special case when  $r_A = e_A$ , the identity permutation, and  $r_B = t \circ e_A$ , where  $t \in T_2$ , and  $f_A$ ,  $f_B$  are two non-increasing functions. We assume that  $f_A$  is the straight line L((1, s), (n, 0)) connecting the two end points (1, s), (n, 0) and  $f_B$  is the combination of the two straight lines with end points  $L_1((1, s), (x, y))$  and  $L_2((x, y), (n, 0))$  which meet at (x, y). We state and prove the following theorems (see figure 4(b) in Section 2 for the special cases n = 500 and s = 100):

**Theorem 1.** Let A, B, C and D be defined as before. Let  $f_A = L$  and  $f_B = L_1 U L_2(L_1 and L_2 meet at <math>(x^*, y^*))$  be defined as above. Let  $r_A = e_A$  be the identity permutation and  $r_B = t \circ e_A$ , where  $t \in T_2$  and t = (i, j). If  $q < x^*$  and (a) i < j < q, (b) q < i < j, (c)  $i < q < j < x^*$ , or (d)  $i < q < x^* < j$ , where max  $\{h_{AB}(i), h_{AB}(j)\} \le y^+ = (1/2)[y^* + f_A(x^*)]$  and  $(1/2)(i + j) > x^*$ , then  $P_{@q}(C) \ge P_{@q}(D)$ . See Appendix A for proof.

**Theorem 2.** Let A, B, C, D,  $r_A$ ,  $f_A$ ,  $r_B$  and  $f_B$  be defined as in Theorem 1. If  $q < x^*$  and either (a), (b), (c) or (d) in Theorem 1 is satisfied, then  $P_{avg}(C) \ge P_{avg}(D)$ . Proof is similar to that of Theorem 1.

# 4. Simulation

In this section, we describe the simulation results for different cases. In each of the cases, we assume the number of documents to be n = 500 and the highest score given to any rank is s = 100. Hence the total number of possible permutations as rank function is 500!. The rank functions rB's are obtained by a random generation process in Case 4.1. In each simulation, we generate ten thousand (10 k) cases of  $r_B$ . In our study, we fix  $f_A$  to be the straight line connecting the two end points (500, 0) and (1, 100). Since  $f_B$  can be any discrete function defined from [1, 500] to [0, 100] which is monotonically non-increasing, we start with a special case of  $f_B$  which is a combination of two straight lines with one turning point ( $x^*$ ,  $y^*$ ). Note that the point (200, 30) is such a turning point for the rank/score function  $f_B$  in figure 4(b) in Section 2. On the other hand, the rank/score function  $f_B$  in figure 4(a) has no such points. Since the problem at issue is combining two ranked lists A and B, we would like to see  $r_A$  and  $r_B$  as arbitrary as possible. Therefore we include a case where  $r_A$  and  $r_B$  are both randomly generated in Case 4.2. These two cases are described in more details as follows:

*Case 4.1* ( $r_A = e_A$  the identity permutation,  $r_B = random$ ). In this case,  $r_A = e_A$ ,  $f_A$  is the straight line connecting (500, 0) and (1, 100). In fact,  $f_A$  has the following formula y

= (-100/499) (x - 500) (See  $f_A$  in figure 4(b) in Section 2). For each permissible turning point  $(x^*, y^*)$  for the rank/score function  $f_B$  we generate 10 k  $r_B$ 's. Then we combine these 10 k ranked lists B's with ranked list A. The results are listed in figure 6 using  $P_{@50}$  and  $P_{\text{avg}}$  respectively. In figure 6(a), the tuples at point  $(x^*, y^*)$  (i.e. (a, b, c)) where a, b and c are the number of cases out of the 10 k cases so that  $P_{@50}(C) < P_{@50}(D), P_{@50}(C) >$  $P_{\emptyset = 50}(D)$  and  $P_{\emptyset = 50}(C) = P_{\emptyset = 50}(D)$  respectively. Likewise, figure 6(b) exhibits the values of (a, b, c) in percentages (out of the 10 k cases) with one decimal point. Figure 6(c) uses  $P_{\text{avg}}$  instead of  $P_{@50}$ . In these cases, only values of (a, b) are used as it rarely happens that  $P_{\text{avg}}(C) = P_{\text{avg}}(D).$ 

*Case 4.2* ( $r_A$  = random,  $r_B$  = random). In this case,  $f_A$  is the same straight line as in Case 4.1 and  $f_B$  has the turning point  $(x^*, y^*)$ . Everything else is the same. We list the results in figure 7(a)–(c).

We note that figures 6 and 7 exhibit certain features which are quite noticeable. One of the most interesting phenomena is that when the turning point  $(x^*, y^*)$  is below the standard line (i.e.  $f_A$ ) at certain locations, the performance of the combination using rank (P(C)) is most likely to be better than that of the combination using score (P(D)). In the case when  $r_A$  is the identity permutation, the results are fairly consistent. Even when  $r_A$  is randomly generated (figure 7),  $P_{avg}(C)$  is greater than  $P_{avg}(D)$  in most of the locations (for turning point for  $f_B$ ). This prompts us to explore the problem, once again, of finding any other predictive variable for the effectiveness of data fusion. In fact, in the previous section (Section 3), we have shown that under the condition that  $f_B$  has the turning point  $(x^*, y^*)$ and  $r_B$  is the single cycle of permutation (i.e. the transposition (i, j) for any  $1 \le i, j \le n$ and  $i \neq j$ ), the combination by rank performs better than combination by score in either  $P_{@q}$  or  $P_{avg}$  cases as long as  $q < x^*$ .

We are also interested in the performance of C and D as compared to those of A and B. The data fusion model and architecture we established in Section 2 in this paper is very helpful in the study of data fusion in information retrieval. The simulation procedure is fairly easy to implement. For example, in the quest to find predictive variables for the effectiveness of data fusion, the two predictive measures identified by Ng and Kantor (1998, 2000) are  $P_l/P_h$  and  $d_k(A, B)$  where  $P_l = \min\{P(A), P(B)\}$  and  $P_h = \max\{P(A), P(B)\}$ . In this paper, we have shown analytically and experimentally that the graphical relation between the rank/score functions  $f_A$  and  $f_B$ ,  $d(f_A, f_B)$ , is an indicator to distinguish P(C) and P(D). The data generated and exhibited in figures 8 and 9 demonstrated that the two parameters  $d(f_A, f_B)$  and  $P_l/P_h$  are, to great extent, barometers to predict the effectiveness of combinations.

Figure 8 lists the change of (a, b, c) along the change of the turning point  $(x^*, y^*)$ , where  $P = P_{@50}, r_A$  and  $r_B$  are randomly generated, and

- $a = \text{number of 10 k cases with } P(C) > \max\{P(A), P(B)\},$   $b = \text{number of 10 k cases with } P(D) > \max\{P(A), P(B)\}, \text{ and }$   $c = \text{number of 10 k cases with min } \{P(C), P(D)\} > \max\{P(A), P(B)\}.$

Figure 9 shows the distribution in percentage of the 10 k cases at (x, y), where x = 0.1 to 1.0 in step of 0.1 and y = (50, 10) to (450, 90) in steps of (50, 10) and

 $\begin{cases} a = \% \text{ of } 10 \text{ k cases with } P(C) > \max\{P(A), P(B)\}, \\ b = \% \text{ of } 10 \text{ k cases with } P(D) > \max\{P(A), P(B)\}, \text{ and} \\ c = \% \text{ of } 10 \text{ k cases with } \min\{P(C), P(D)\} > \max\{P(A), P(B)\}. \end{cases}$ 

Figures 9(a)–(d) deal with  $P_{@50}$  and  $P_{avg}$  respectively. All these figures have  $P_l/P_h$  as the *x*-coordinate.

#### 5. Discussion and future work

In this paper, we have established a framework (see figure 5) for analysis and simulation in the study of data fusion in the information retrieval domain by defining rank function and score function and using the concept of a rank/score function. Every evidence (from query formulation, retrieval schema or system) is represented as a ranked list (such as A) with three functions:  $r_A(x) = rank$  function,  $s_A(d) = score$  function and  $f_A = rank/score$ function. The rank function  $r_A$  is viewed as a permutation of  $[d_n] =$  the set of *n* documents. Using the concept of a Cayley graph, we consider a rank function  $r_A$  (of *n* documents) as a node (and a permutation of [n]) of the Cayley graph,  $(S_n, T)$ , where  $S_n$  is the symmetric group of order *n* and *T* is a generating set of  $S_n$  excluding the identity permutation *e*.

Recall from Remark 1.6, Definition 2.4 and figure 5, rank function  $r_A$  and score function  $s_A$  are defined respectively from N to D and from D to  $R^+$ . Hence the rank/score function is obtained as  $f_A = s_A \circ r_A$ . In some application domains, the rank function  $r_A^*$  may be defined as the inverse function of  $r_A$  (i.e.: from D to N). In such a case, the rank/score function would be  $f_A^* = s_A \circ r^{*-1}$  (i.e.:  $f_A^* \circ r_A^* = s_A$ ).

Our current study is the first of a series of investigations exploring the central question of why and how data fusion (or evidence combination) should be done. We have started with some specific cases when the rank/score function  $f_A$  = straight line and  $f_B$  = semi-linear with one point of intersection  $(x^*, y^*)$  (see Sections 3 and 4) even though both functions can be any discrete function defined from [1, 500] to [0, 100] which is monotonically non-increasing (see figure 4(a)). In Section 5.3(d), we will discuss that the condition n = 500 can be relaxed to include any constant n. We have proved in Section 3 that if  $r_A = e_A$ , the identity permutation,  $r_B = t \circ e_A$  where  $t \in T_i$  and  $q < x^*$  with certain conditions, then  $P_{@q}(C) \ge P_{@q}(D)$ . Then in Section 4, applying both cases (i)  $r_A = e_A$ ,  $r_B =$  random, and (ii)  $r_A$ ,  $r_B$  are random to all 81 points of intersection  $(x^*, y^*)$  and generating the thousand (10 k) permutations for each random case, we have found several interesting phenomena. All these analytical and simulation results, summarized in Sections 5.1 and 5.2, strongly support those findings observed by previous researches surveyed in Section 1 as highlighted in Remarks 1.1–1.4. Section 5.3 discusses our future work on several directions as suggested in the current study.

# 5.1. Combination using rank vs. score

The thrust of our approach is that we are able to define and extract the rank/score function  $f_A$  from a ranking procedure A which gives the rank function  $r_A$  and score function  $s_A$ . On the other hand, the score function  $s_A$  can be obtained as  $s_A(d) = (f_A \circ r_A^{-1})(d) = f_A(r_A^{-1}(d)) = f_A(x)$  if  $r_A$  and  $f_A$  are known, where  $r_A(x) = d$ , d is a document ranked by  $r_A$  as rank order x. This differentiation between  $f_A(x)$  (defined on ranks) and  $s_A(d)$  (defined on documents) enables us to characterize different ranking procedures (algorithms or systems), and then to better quantify the differences between them (see Remarks 1.1 and 1.2). Our results in Sections 3 and 4 with respect to  $(x^*, y^*)$ ,  $(y^* < -\frac{1}{5}x^* + 100)$ , (n = 500, s = 100, q = 50) confirmed the observations made by previous researchers and summarized in Remark 1.1 (see Belkin 1994, 1995) and Remark 1.2 (see Lee 1997). Specifically, we have demonstrated in our simulation that when  $\sum_{x=1}^{500} |(f_A(x) - f_B(x))|$  is big enough, combination using ranks performs better than combination using scores under certain conditions. In particular, we have shown analytically in Theorems 1 and 2 that when the difference between  $r_A$  and  $r_B$  is a transposition (i, j) with certain conditions and  $q < x^*$  with certain conditions, the performance of rank combination is at least as good as that of score combination.

#### 5.2. Effectiveness of combination

Various techniques and experiments have been performed to study the effectiveness of combining two or more systems (formulations, algorithms, or different runs) (Aslam et al. 2003, Belkin 1993, 1994, 1995, Hsu et al. 2003, Lee 1997, Lyons et al. 2003, Marden, 1995, Ng and Kantor 1998, 2000, Vogt and Cottrell 1999). These include the progressive combination of query formulations and the linear combination (LC) model for fusion of IR system by scoring each document with a weighted sum of the scores from each of the component systems (Vogt and Cottrel 1999) and the study by Ng and Kantor (1998, 2000) which identified two predictive variables: the Kendall distance and the performance ratio (see Remarks 1.3 and 1.4). The Kendall distance  $d_K(r_A, r_B)$  measures the degree of concordance between two different rank lists  $r_A$  and  $r_B$ . The performance ratio  $P_l/P_h$  measures the similarity of performance of the two IR schemes A and B. Our simulation results (see figures 9(a)–(c)) are in conformity with those by Ng and Kantor on the performance ratio  $P_l/P_h$ . We have run ten thousand random cases for each of the nine points of intersection  $(x^*, y^*)$ , where  $(x^*, y^*) = (50 t, 10 t)$  and  $1 \le t \le 9$  (see figures 9(a)–(d)).

When considering the positive fusion cases of the combination of different rank lists A and B, the distribution of the positive cases is clustered around  $P_l/P_h \sim 1$  for each of the three comparisons regarding effectiveness of the combinations: P(C) vs. max $\{P(A), P(B)\}$ , P(D) vs. max $\{P(A), P(B)\}$ , and min $\{P(C), P(D)\}$  vs. max $\{P(A), P(B)\}$ , where C and D are combination of A and B using rank and score respectively. As to the Kendall distance  $d_K(r_A, r_B)$ , we have not attempted to find such pattern in our simulation. However, the simulation results for Case 4.2 discussed in Section 4 and exhibited in figure 8 demonstrated that the graphical behaviors of the rank/score function might be a feasible predictive variable for the effectiveness of combination.

#### 5.3. Future work

We have discussed, in Section 4.1, that when  $r_A = e_A$  and  $r_B =$  random we have P(C) > P(D) (either @50 or on average) (see figures 6(a)–(c)) for most of the cases at point of intersection  $(x^*, y^*)$ , where  $(y^* < -\frac{1}{5}x^* + 100)$ . It is interesting to note that when  $(y^* > -\frac{1}{5}x^* + 100)$ , the situation changes and in fact it becomes the opposite. At the points  $(x^*, y^*)$  of intersects where  $(y^* = -\frac{1}{5}x^* + 100)$ , the situation varies and in majority of the 10 k cases P(C) = P(D) when performance@50 is used. When  $r_A$  and  $r_B$  are generated at random, slightly higher percentage of the 10 k cases have  $P_{avg}(C) > P_{avg}(D)$  than  $P_{avg}(D) > P_{avg}(C)$  (see figure 7(c)). However, when performance@50 is used, no apparent pattern can be drawn (see figure 7(a) and (b)).

The current study suggests several problems worthy of further study and several issues that require further investigations. We summarize as follows:

- (a) Let  $G_{@q}(X) = P_{@q}(X) \max\{P_{@q}(A), P_{@q}(B)\}\)$ , where X = C or D. Let  $G_{@q}(C,D)$ =  $P_{@q}(C) - P_{@q}(D)$ .  $G_{avg}(X)$  and  $G_{avg}(C, D)$  are defined in a similar fashion. In this paper, we have studied the behavior of these parameters under the condition that  $f_A$ is linear and  $f_B$  is semi-linear with one point of intersection. One direction to pursue is to study the two parameters  $G_{@q}(X)$  and  $G_{@q}(C, D)$  when  $f_A$  is linear and  $f_B$  is piecewise-linear with k points of intersection, or the more general cases, when  $f_A$ and  $f_B$  are piecewise linear or are in more general situation of being non-increasing monotonic functions.
- (b) In our computation of  $s_C$  and  $s_D$ , we simply take the average of the ranks and scores of *A* and *B* respectively (see Definitions 2.6 and 2.7). However, different weights can be assigned to each individual schema and different ways of combinations can be performed in the combination of two or more schemas. Several authors (see Dwork et al. 2001, Fagin et al. 2003, Hsu and Palumbo 2004, Ibraev et al. 2001, Kantor 1998 and Vogt and Cottrell 1994) studied the effectiveness of different weighting assignments and different methods of combination. Our goal in this direction is to extend our results to the weighted combination for *A* and *B* (assigning weights  $\alpha$  and  $1 - \alpha$  to *A* and *B* respectively, where  $0 < \alpha \le 1$ ) and for more than two schemas. In (2004), Hsu and Palumbo studied data fusion in the Cayley graph  $G(S_n, T_1)$  to combine *A* and *B* using weights  $\alpha$  at an increment of 0.1. We also aim to extend our results to compare rank vs. score combinations using different methods of combination such as Markov chain or other non-linear methods.
- (c) The current paper has defined the rank/score function  $f_A$  (for a schema A) and established an abstract sample space  $S_n$  (for a schema A with rank list  $r_A = [A_1, A_2, ..., A_n]$ on the set of *n* documents) (our examples use n = 500). We have observed (figure(9)(a)– (d)) that positive cases exist when  $P_l/P_h$  is close to 1, but have not yet attempted to find any correlation between positive cases and the metric  $d_K(r_A, r_B)$  (the Kendall distance). Kantor (1998) has proposed a geometric model which treats  $P_l$ ,  $P_h$  and  $P_{ideal}$  (a perfect solution) as three points in an abstract space. Then Ibraev et al. (2001) showed that in the ideal case, the performance of data fusion for a pair IR schemas may be approximated by a quadratic polynomial. From the equation of the curve, it follows that for effective DF the weight of the better schema must be greater than that of the worse schema.

However, some anecdotal evidence suggest that there exist cases where DF is effective when the worse schema has more weight. In our study of DF effectiveness, we can use the rank space  $S_n$  with  $d_K(r_A, r_B)$  as the distance function. In fact, we can restrict our space to the hyperplane of  $S_n$  consisting of all points  $r_A$ 's =  $[A_1, A_2, ..., A_n]$  with  $\sum_{i=1}^n A_i = \frac{n(n+1)}{2}$ . We will investigate DF effectiveness using our Cayley graph model  $(S_n,T_1)$  and  $d_K(r_A, r_B)$  in the hyperspace of  $\sum_{i=1}^n A_i = \frac{n(n+1)}{2}$  and compare our results with the geometric model studied by Kantor et al (2001) and Kantor (1998). Work along this line has been performed by Hsu and Palumbo (2004) with respect to using  $S_n$  as the rank space and  $\Gamma(S_n, T_1)$  as the Cayley graph model. While Kantor et al's approach is considered as a geometric model, the approach of Hsu and Palumbo (2004), and Hsu et al. (2002) using the Cayley graph  $(S_n, T_1)$  as a rank space is rather combinatorial.

- (d) We note that in our simulation we use n = 500. However this condition could be relaxed to include any constant n. The cut of value for precision was chosen to be q = 50 which is 10% of the n = 500. This ratio is very much related to the real situation of information retrieval systems. We also note that in the real situation the range for  $s_A$  and  $s_B$  may vary. It is important that these two functions have to be normalized to some common range (in our case, we use s = 100 or 1.00) before they can be combined to generate C or D. In general, normalization of the score functions of two or more schemas is a vital step and should have a great impact on the effectiveness of the combinations.
- (e) We note that framework proposed and results obtained in this paper for information retrieval can be applied in other domains also. The rank and fuse (RAF) approach for target tracking in CCTV surveillance (Hsu et al. 2003, Lyons et al. 2003) and rank and combine (RAC) method for microarray and gene expression data analysis in bioinformatics (Chuang et al. 2004, Hsu and Palumbo 2004) are two examples of this application.

## Appendix A

#### Proof of Theorem 1

We divide the problem into three cases according to the relative positions of *i* and *j* with respect to *q*: (a) i < j < q, (b) q < i < j, and (c) i < q < j. In the first two cases, it is easy to see that  $P_{@q}(C) = P_{@q}(D)$ , since the swap of *i* and *j* (when *i*, *j* are less than or greater than *q*) does not make any difference to the performance of *C* or *D*. Therefore, we consider only case (c) from now on where i < q < j. Since  $q < x^*$ , we then divide case (c) into two subcases:

Subcase (c) (i):  $i < q < j < x^*$ . We have  $s_A(j) - s_B(j) > s_A(i) - s_B(i)$  since the decrease of  $s_B(x)$  is faster than that of  $s_A(x)$ .

Subcase (c) (ii):  $i < q < x^* < j$ . In this case,  $s_A(j) - s_B(j)$  can be greater than, equal to, or less than  $s_A(i) - s_B(i)$  depending on how big j is.

In order to prove these two cases, we treat  $r_A$ ,  $r_B$ ,  $s_A$ ,  $s_B$ ,  $r_C$ ,  $r_D$ , and other related functions or permutations as arrays on the index set [n]. Then we have  $r_A(i) = i$ ,  $r_A(j) = j$  and  $r_B(i) = j$ ,  $r_B(j) = i$ . Hence we have  $g_{AB}(i) = 1/2(i + j) = g_{AB}(j)$ . After sorting the

466

array  $f_{AB}$  into ascending order to become  $s_g$ , we have

$$s_g\left(\left\lfloor \frac{i+j}{2} \right\rfloor\right) = \frac{1}{2}(i+j) = s_g\left(\left\lceil \frac{i+j}{2} \right\rceil\right).$$

Therefore  $r_c(\lfloor \frac{i+j}{2} \rfloor) = i$  and  $r_c(\lceil \frac{i+j}{2} \rceil) = j$ . The values for  $h_{AB}(i)$  and  $h_{AB}(j)$  can be calculated using formula (3) and (4). Then the question is: which of the two numbers  $h_{AB}(i)$  and  $h_{AB}(j)$  is bigger than the other?

In Subcase (c) (i), with  $s_A(j) - s_B(j) > s_A(i) - s_B(i)$ , we have  $h_{AB}(j) > h_{AB}(i)$  by Definition 2.7. After sorting the array  $h_{AB}$  into descending order to become  $s_g$ , we have  $s_h(i') = h_{AB}(j)$  and  $s_h(j') = h_{AB}(i)$  for some i', j' in [i, j] with i < i' and j' < j. Hence we have  $r_D(i') = j$  and  $r_D(j') = i$ . Hence we have the following situation for subcase (c) (i):

[ <i>n</i> ]:	$1, 2, 3, \ldots, i, \ldots, i', \ldots, \lfloor \frac{i+j}{2} \rfloor, \lceil \frac{i+j}{2} \rceil, \ldots, j', \ldots, j, \ldots, x^*, \ldots, n$
$r_C(x)$ :	$d_1, d_2, d_3, \ldots, d_i, d_j, \ldots, d_n$
$r_D(x)$ :	$d_1, d_2, d_3, \ldots, r_D(i), \ldots, d_j, \ldots, \ldots, d_i, \ldots, r_D(j), \ldots, d_n$

Recall that we have i < q < j in this case. If  $q \in ([i, i']U[j', j])$ , the theorem holds because  $P_{@q}(C) = P_{@q}(D)$ . If  $q \in ([i', \lfloor \frac{i+j}{2} \rfloor] \cup [\lceil \frac{i+j}{2} \rceil, j])$ , then  $P_{@q}(C) > P_{@q}(D)$ .

In Subcase (c) (ii) where  $i < q < x^* < j$ , we have three possibilities depending on  $s_A(j) - s_B(j)$  is greater than, equal to, or less than  $s_A(i) - s_B(i)$ . When  $s_A(j) - s_B(j) > s_A(i) - s_B(i)$ , we have  $h_{AB}(j) > h_{AB}(i)$ . Hence the proof is similar to previous case, Subcase (c) (i). When  $s_A(j) - s_B(j) = s_A(i) - s_B(i)$ , we have  $h_{AB}(j) = h_{AB}(i)$  by Definition 2.7. It follows that  $r_D(i') = d_i$  and  $r_D(i' + 1) = d_j$  where  $i' \in (i, j)$  and i < i' < j. In this case, no matter where q is, we have  $P_{@q}(C) \ge P_{@q}(D)$ . For the last possibility where  $s_A(j) - s(B) < s_A(i) - s_B(i)$ , we have  $h_{AB}(j) < h_{AB}(i)$  by Definition 2.7. It follows that  $r_D(i') = d_j$  where i < i' < j. In this case, no matter where q is, we have  $P_{@q}(C) \ge P_{@q}(D)$ . For the last possibility where  $s_A(j) - s(B) < s_A(i) - s_B(i)$ , we have  $h_{AB}(j) < h_{AB}(i)$  by Definition 2.7. It follows that  $r_D(i') = d_i$  and  $r_D(j') = d_j$  where i < i' < j' < j. Hence we have the following situation for the third possibility of Subcase (c) (ii):

[ <i>n</i> ]:	$1, 2, 3, \ldots i, \ldots i', \ldots, \lfloor \frac{i+j}{2} \rfloor \lceil \frac{i+j}{2} \rceil, \ldots j', \ldots j, \ldots \ldots n$
$r_C(x)$ :	$\ldots, \ldots, d_i, \ldots, d_j, \ldots, \ldots$
$h_{AB}(x)$ :	$\ldots, h_{AB}(i), \ldots, h_{AB}(j), \ldots, h_{AB}(j), \ldots$
$s_h(d)$ :	$\ldots, h_{AB}(i), \ldots, h_{AB}(j), \ldots, h_{AB}(j), \ldots$
$r_D(x)$ :	$\ldots, r_D(i), \ldots, d_i, \ldots, \ldots, d_j, \ldots, r_D(j), \ldots$

Since in this subcase  $h_{AB}(i) > h_{AB}(j)$ , i < i' < j' < j and  $i < q < x^* < j$ , we have either  $i' < x^*$  or  $i' > x^*$ . Let  $(x^*, y^+)$  be the middle point between  $(x^*, y^*)$  and  $(x^*, f_A(x^*))$ . By the assumption (d) in the Theorem 1 that max  $\{h_{AB}(i), h_{AB}(j)\} = h_{AB}(i) \le y^+$ , we have  $r_D(i') = d_i$ , where i' is such that  $s_h(i') = h_{AB}(i)$  and  $i' > x^*$ . On the other hand we have  $\frac{i+j}{2} > x^*$ . Combining these two inequalities  $i' > x^*$  and  $\frac{i+j}{2} > x^*$  (note:  $r_C(\frac{i+j}{2}) = d_i$ ) together with the assumption  $q < x^*$  in this case, we have  $P_{@q}(C) = P_{@q}(D)$ . This completes the proof of the theorem.
